

Estimating Silage Inventories

When planning your winter feeding programs, you'll need to estimate your inventories of silage to determine the optimum amounts to include in your rations. Here are some guidelines to help you make those estimates:

Counting loads at harvest

One common method of estimating the amount of silage harvested is to multiply the number of loads brought in from the field by the average load size. If you are hauling in more than one truck or wagon, you'll have to maintain a count of each, assuming they each carry different amounts of silage. Load sizes can be calculated by multiplying the volume of silage in the forage box by its bulk density. For example, if your forage wagon measures 8 feet wide by 16 feet long and you fill it to an average depth of 6 feet, then the volume is:

$$8 \text{ feet} \times 16 \text{ feet} \times 6 \text{ feet} = 768 \text{ cubic feet (ft}^3\text{)}.$$

Trials at the University of Wisconsin showed that forage box bulk densities varied from 4.6 to 5.7 pounds of dry matter (DM) per cubic foot (lb DM/ft³) for a variety of grass, legume and cereal silage crops. The average bulk density was very close to 5 lb DM/ft³. Using this figure, the amount of DM in the wagon above would be:

$$768 \text{ ft}^3 \times 5 \text{ lb/ft}^3 = 3840 \text{ lb} = 1.92 \text{ tons}.$$

This method is subject to a good deal of error. The Wisconsin trials indicated that there was a 68% probability that DM bulk density of a crop would actually be between 4.2 and 5.8 lb/ft³. Combine this uncertainty with normal variation in load sizes and it's not hard to imagine that your estimate of the total amount of silage DM harvested could be out by plus or minus (±) 20%.

An alternative and more accurate method is to estimate the amount of silage that actually ends up in the silo. Here's how:

Estimating horizontal silo inventory

Measuring volume is the most difficult problem in estimating inventories in horizontal silos. The easiest way to do this is to make a drawing and approximate the shape of the stack or bunker with a number of triangles and rectangles. In the example shown in figure 1, the total volume of silage is the sum of the volume in the body plus the volume in the wedge. Body volume is:

$$\text{BODY HEIGHT} \times \text{BODY LENGTH} \times \text{WIDTH}$$

Wedge volume is:

$$\frac{\text{WEDGE HEIGHT}}{2} \times \text{WEDGE LENGTH} \times \text{WIDTH}$$

Dennis Darby, a farm structures engineer with Alberta Agriculture, measured silage densities in 21 bunker silos in southern and central Alberta. Here's what he found:

- DM density of bunker silage is independent of moisture content. If 2 samples of the same silage have different moisture contents, the wetter sample will have the higher wet bulk density. But, when these 2 samples are dried, their DM bulk densities will be the same.
- In horizontal silos, there is no significant variation in DM bulk density from top to bottom.
- On average, the DM density of barley silage (14.5 lb/ft³) was lower than that of grass-legume silage (16.3 lb/ft³).

Therefore, calculation of silage inventories in horizontal silos simply involves multiplying total volume by the DM bulk density for the particular type of crop. When using these inventories to determine ration inclusion rates, you should plan to use a minimum of 4 inches off the face of the silage each day (more in warm weather) to prevent spoilage. Calculate the amount of DM this represents by using body height and width.

Figure 1 : Dimensions required to estimate silage volume in a bunker silo.

Estimating vertical silo inventories

In contrast to horizontal silos, it is a relatively simple matter to calculate silage volume in an upright tower:

$$3.14 \times \left[\frac{\text{silo diameter}}{2} \right]^2 \times \text{silage depth}$$

However, in vertical silos, bulk density is influenced by silage depth, moisture content and silo diameter. Since these relationships are complex, it is not possible to estimate inventory by simply multiplying volume by a uniform density estimate. Table 1 provides DM capacities for vertical silos, based on work done at the University of Guelph. To use the table, choose the diameter of your silo, then interpolate between values in that section of the table. For example, if you have 55 feet of 65% moisture barley silage in an 18 foot tower:

- if the settled depth of silage were 50 feet, DM inventory at 65% moisture would be roughly midway between the inventory at 60% moisture and that at 70% moisture – about 59 tonnes;
- similarly, if silage depth were 60 feet, DM inventory at 65% moisture would be about 72.5 tonnes – midway between 80 and 65;
- since the 65% moisture level is midway between 60 and 70%, you can estimate a DM inventory midway between 59 and 72.5 tonnes – about 66 tonnes.

If you silage is a grass-alfalfa mix, you can also interpolate between values for straight alfalfa and straight grass silages.
